Abstract

A recently developed model for excitation and detection mechanisms of silicon resonant sensors is experimentally verified by applying it to practical devices. Various system aspects of resonators with piezoelectric and electrostatic excitation/detection come into focus. The experimental results agree reasonably well with simulation results obtained by the model.

1. Introduction

Silicon resonant sensors [1, 2] are suitable for measurement of mechanical quantities (force, pressure, acceleration, etc.) with high precision. The operating principle of silicon resonant sensors is that the resonance frequency of a micromachined silicon structure (for example, a prismatic beam) shifts as the measurand changes. The resonance frequency is the sensor output signal. Recently, we developed a systematic unifying model to describe the excitation and detection mechanisms of this sensor family [3]. The model is based on a system approach: the resonator, including the transducers for excitation/detection, is regarded as a full electromechanical system. In ref 3, the model is derived, and a comparative review of excitation and detection mechanisms for micromechanical resonators is given. In this paper, we demonstrate the practical applicability of the model.

2. The sensor model

In order to activate and sense the vibration, one or more electromechanical transducers for excitation and detection have to be incorporated in the sensor system. For this purpose, various mechanisms are suitable. Here, we restrict ourselves to mechanisms of the reversible type. Energy can be exchanged with the system through the transducers. The energy flow through a single transducer is characterized by an intensive variable (e.g., a voltage \( u \)) and a corresponding extensive variable (e.g., a charge \( q \)). The power flow equals the product of the extensive variable and the time derivative of the intensive variable, which is called extensity flow variable, or just flow. Every transducer serves as a power port of the system. The number of electrical ports of the system equals the number of electromechanical transducers.

The system has also mechanical ports. Since the mass, stiffness and damping of the resonator are distributed, an infinite number of mechanical ports is required. An elegant discretization is obtained when the mechanics of the resonator is described in terms of its eigenstates, also called vibration modes. In that case, the modal displacements \( y \), are the extensive variables, and the modal forces \( P \), are the intensive variables. The modal approach is similar to a Fourier series: the shape of the vibrating resonator is expanded in the mode shapes.

The number of mechanical ports of the system equals the number of modes taken into account. Since resonant sensors are operated near resonance, good approximations can be obtained with only a few mechanical ports.

Thus, the total system has \( n + m \) energy ports, where \( m \) stands for the number of electromechanical transducers and \( n \) for the number of modes taken into account. A bond-graph representation of the sensor system is shown in Fig. 1. Small harmonic variations around an equilibrium state can be described by the matrix equation:

\[
\begin{bmatrix}
\dot{\mathbf{u}} \\
\dot{\mathbf{P}}
\end{bmatrix} =
\begin{bmatrix}
\mathbf{E} & \mathbf{C} \\
\mathbf{C}^t & \mathbf{M}
\end{bmatrix}
\begin{bmatrix}
\mathbf{q} \\
\mathbf{y}
\end{bmatrix}
\]

(1)

where \( \mathbf{E} \), \( \mathbf{M} \) and \( \mathbf{C} \) are an electrical, a mechanical and an electromechanical coupling matrix, respectively. \( \dot{\mathbf{u}} \) and \( \dot{\mathbf{q}} \) are vectors of length \( m \), and \( \dot{\mathbf{P}} \) and \( \dot{\mathbf{y}} \) are vectors of length \( n \). The dot indicates differentiation with respect to time and the overbar indicates amplitude. Equation (1) is called the constituent equation of the system.

### 3. Electrical transfer function of a piezoelectric resonator

At the MESA Institute, research is performed on a piezoelectrically operated resonant force sensor [4]. The sensor has two electromechanical transducers for excitation and detection. The transducers consist of a thin piezoelectric ZnO film sandwiched between a tungsten and an aluminum electrode. This three-layer structure is placed on top of the resonator (see Fig 2). Only the first two modes of vibration are taken into account. Hence, the system model has two electrical and two mechanical ports.

The mechanical submatrix \( M \) of the constituent eqn (1) merely consists of the mechanical spring effect of the modes. Off-diagonal elements of this matrix, as well as the electrical submatrix \( E \), are zero. Diagonal elements of \( E \) represent the impedance of the capacities of the ZnO layers. Finally, the coupling matrix \( C \) reflects the electromechanical transducing capabilities of the excitation/detection elements. Important parameters in the matrix elements of \( C \) are the piezoelectric coefficient, \( d_{31} \), of the ZnO, the intrinsic coupling factor of the ZnO, the thickness of the piezoelectric film and a geometrical factor which is a measure of the efficiency of a transducer to couple energy to or from a specific mode. For the exact details concerning the matrix elements we refer to refs 3 and 5.

The system is described by eight variables four intensive and four flow variables. To calculate the electrical transfer function, i.e., the ratio \( \tilde{u}_2/\tilde{u}_1 \), seven equations are required. Four equations are obtained from the constituent equation. The other three are phenomenological equations. They describe how the power ports are loaded or controlled by the outside world. The two mechanical ports are loaded by viscous friction forces (which can be obtained from modal quality factors) and inertia (the modal masses). The electrical port used for the detection is loaded by a resistance \( R_2 \). The excitation port is controlled by a voltage source.

Simulation results of the transfer function \( \tilde{u}_2/\tilde{u}_1 \) are given in Fig 3. Simulations are performed for three values of \( R_2 \), namely, \( R_2 = 0 \) \( R_{\text{char}} \), \( R_2 = R_{\text{char}} \) and \( R_2 = 10 R_{\text{char}} \). \( R_{\text{char}} \) is the modulus of the impedance of the detection transducer at the first resonance frequency. \( R_{\text{char}} = 1/\omega_1 C_{\text{ZnO}} \), where \( \omega_1 \) is the angular resonance frequency of the first mode, and \( C_{\text{ZnO}} \) is the capacity of the ZnO transducer.

The load impedance \( R_2 \) forms a high pass filter in combination with the capacity of the transducer \( C_{\text{ZnO}} \). The turnover frequency of this inherent filter is given by \( f_{\text{to}} = 1/(2\pi C_{\text{ZnO}} R_2) \). The filter characteristic is clearly visible in Fig 3. If \( R_2 \ll R_{\text{char}} \), the resonance peaks are on the 20 dB/decade flank of the filter and the loop of the second mode is larger than that of the first mode. For \( R_2 \gg R_{\text{char}} \), both resonance frequencies are higher than the turnover frequency and the loop of the first mode is the larger one. Another observation is that the phase at resonance shifts from 0° to -90° as the load impedance varies from \( R_2 \ll R_{\text{char}} \) to \( R_2 \gg R_{\text{char}} \). Considerations like this are of the utmost importance when designing feedback electronics for the oscillator.

The above characteristics have been experimentally verified. Figure 4 shows the measured polar plots for frequencies around the first resonance frequency. The rotational orientation and the sizes of the resonance loop are determined by position of the turnover frequency of the filter with respect to the first resonance frequency. The aforementioned high-pass frequency characteristic manifests itself by a hemicycle in the first quadrant of the polar plot. This is shown in Fig 5.
The impedance of this device, measured at the electrical port, can be written as

\[ Z(\omega) = \frac{1}{\omega^2} - \frac{1}{j\omega C_1} + \frac{1}{j\omega C_2} \left( \frac{1}{\omega_1^2} - \frac{1}{\omega_2^2} \right) \]

(2)

where the constants \( C_1 \) and \( C_2 \) are composed of piezoelectric, electric and mechanical properties of ZnO and the dimensions/shape of the transducer and the resonator \( C_1 \) and \( C_2 \) can be obtained from the matrix elements of the constitutive equation. For the exact expressions of \( C_1 \) and \( C_2 \) we refer to refs 3 and 5.

The first term of eqn (2) results in a straight line extending along the negative imaginary axis of the polar impedance plot (see Fig 7). The second term only contributes near resonance and results in a loop. Properties of the ZnO can be obtained from the diameter of this loop, provided that the dimensions of the structure and its \( Q \) factor are known. The loop diameter can be interpreted as a figure of merit for piezoelectrically operated resonators.

Two samples were measured. A typical impedance measurement is shown in Fig 7. It is noteworthy that the measured diameter of the loop was corrected for the series and parallel capacitances, which are the result of an SnO$_2$ layer and the extension of the film on the substrate, respectively (see Fig 6). Table 1 summarizes the results. Literature values of bulk ZnO are also included.

*Value determined using the \( s_{11} \) value of bulk ZnO
The ZnO was sputtered with a substrate temperature of 425 °C, an RF power of 1800 W for 1 min, and 1000 W for the remainder of the time (2 h). The oxygen pressure was 0.5 Pa. The thickness of the film was 3.68 μm. It was assumed that the whole film shows a homogeneous piezoelectric activity.

5. Loaded Qs

Since high Q resonant sensors generally have a high resolution, a high Q is usually pursued. The Q of the resonance, being defined as the ratio of the stored vibration energy and the periodically dissipated energy, is often determined by mechanical considerations. However, energy can be dissipated not only at mechanical ports, but also at electrical ports by resistively loading the transducers. In this manner, it is possible that a resonator exhibits a Q which is considerably lower than the Q based on mechanical considerations.

The Q, based on dissipation in the electrical domain, of a resonator system with one vibration mode and one transducer is given by [3]

$$Q_{el} = \frac{1}{k^2} \frac{|1 + E|/Z_{load}|}{|E| \text{Re}(1/Z_{load})}$$

where the electromechanical coupling factor, defined as $k^2 = C^2/ME$, was supposed small. The minimum $Q_{el}$ is obtained for $Z_{load} = |E|$ and equals $Q_{el,\text{min}} = 2/k^2$. At this load impedance, maximum signal-to-noise ratio is obtained. In most cases, the coupling factor is rather small and $Q_{el}$ is overruled by the Q based on mechanical considerations. For example, the piezoelectric force sensor (Section 3) has a coupling factor $k = 0.01$, which makes $Q_{el,\text{min}} = 2 \times 10^4$. However, it is well known that the coupling factor of a resonator driven by an electrostatic air-gap mechanism [3] can be varied from 0 to 1 by increasing the bias voltage from 0 to the pull-in voltage. This is shown in Fig. 8.

Figure 9 shows experimental results of a electrostatically operated resonator, the load impedance of which was varied. Clearly, the measured Q is limited by dissipation in the electric domain (the mechanically based Q was approximately 500). The bias voltage was set at 90% of the pull-in voltage, resulting in a coupling factor $k = 0.7$. This would imply a minimum $Q_{el} = 2/k^2 = 5$, however, due to parasitic capacitances the load is not purely resistive. A complex load results in a higher $Q_{el,\text{min}}$ [5].

6. Conclusions

Excitation and detection mechanisms should be regarded as integral parts of silicon resonant sensor systems. A recently developed model has been verified by various experiments, emphasizing system aspects. The model appears to be a powerful tool to describe the functioning of silicon resonant sensors and their interaction with the environment.
